NASA STI Program . . . in Profile

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- TECHNICAL PUBLICATION. Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- TECHNICAL MEMORANDUM. Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- CONTRACTOR REPORT. Scientific and technical findings by NASA-sponsored contractors and grantees.

- CONFERENCE PUBLICATION. Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- SPECIAL PUBLICATION. Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- TECHNICAL TRANSLATION. English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at *http://www.sti.nasa.gov*

- E-mail your question to *help@sti.nasa.gov*

- Fax your question to the NASA STI Information Desk at 443–757–5803

- Phone the NASA STI Information Desk at 443–757–5802

Abstract

During the past two decades the occurrence of ice accretion within commercial high bypass aircraft turbine engines under certain operating conditions has been reported. Numerous engine anomalies have taken place at high altitudes that were attributed to ice crystal ingestion such as degraded engine performance, engine roll back, compressor surge and stall, and even flameout of the combustor. As ice crystals are ingested into the engine and low-pressure compression system, the air temperature increases and a portion of the ice melts allowing the ice-water mixture to stick to the metal surfaces of the engine core. The focus of this paper is on estimating the effects of ice accretion on the low-pressure compressor (LPC), and quantifying its effects on the engine system throughout a notional flight trajectory. In this paper it was necessary to initially assume a temperature range in which engine icing would occur. This provided a mechanism to locate potential component icing sites and allow the computational tools to add blockages due to ice accretion in a parametric fashion. Ultimately the location and level of blockage due to icing would be provided by an ice accretion code. To proceed, an engine system modeling code and a mean line compressor flow analysis code were utilized to calculate the flow conditions in the fan-core and low-pressure compressor and to identify potential locations within the compressor where ice may accrete. Note that there is a baseline value of aerodynamic blockage due to low velocity air near the compressor inner and outer walls and blade surfaces (boundary layer blockage). There is also a blockage due to the blade metal thickness. In this study, the "additional blockage" refers to blockage due to the accretion of ice on the metal surfaces. Once the potential locations of ice accretion are identified, the levels of additional blockage due to accretion were parametrically varied to estimate the effects on the low-pressure compressor blade row performance operating within the engine system environment. This study includes detailed analysis of compressor and engine performance during cruise and descent operating conditions at several altitudes within the notional flight trajectory. The purpose of this effort is to develop the codes to provide a predictive capability to forecast the onset of engine icing events, such that they could help in the avoidance of these events.

It has been reported that ice crystal accretion in gas turbine engines is dependent on the amount of mixed phase conditions (liquid and solid) that exist. In addition, the problem of ice accretion is highly multi-disciplinary, since it involves heat transfer from the air to the compressor metal surfaces. The first phase of this study focuses on addressing the thermodynamic cycle through the engine system code and the mean line flow analysis through the compressor through a flight trajectory. The second phase of this study focuses on the ice particle physics in the flow field that was computed in the first phase.

Nomenclature

Variable Description of COMDES Compressor Code Output

Area1	Rotor leading edge annular area, $in.^2$
A1/A*	Ratio of annular area at the rotor leading edge to the choke area
A*	Choke area of rotor, $in.^2$
AeroBl	Aerodynamic blockage (e.g., 0.98 = 2% blockage)
AthrRotor	Throat area of rotor, $in.^2$
Alfa	Absolute flow angle at stator exit, degrees
Abs MACH	Absolute Mach number
Beta BLADE	Blade angle, degrees
B2 axial	Rotor exit height in axial direction, in.
BetaFlo	Relative flow angle, degrees
BetaBlade	Rotor blade angle, degrees
Beta FLO	Relative flow angle, degrees
C	Absolute velocity, ft/s
ChokeMargin	Choke margin of rotor
Cu	Tangential component of absolute velocity at rotor leading edge, ft/s
Cm	Meridional component of velocity at rotor leading edge, ft/s
Cp	Specific heat at constant pressure
CFM	Volumetric flow rate, ft^3/min
DelRCu	Angular momentum change through blade
Del Enthalpy	Enthalpy rise
Del_H/U^2	Head coefficient (Enthalpy rise/tip speed squared)
Del T	Total temperature rise, R
Deviat	Flow deviation angle from blade trailing edge, degrees
Diff Fct	Diffusion factor
DIFF LOSS	Diffuser, or stator loss coefficient
Efficiency	Efficiency, adiabatic
EffAVG	Rotor average efficiency, adiabatic
GAMMA	Ratio of specific heats (Cp/Cv).
GHP	Horsepower
Incid	Rotor leading edge incidence angle, degrees
NBLAD	Number of rotor blades
Ns	Specific speed
Ns nondim	Specific speed, non-dimensional
OPR	Overall Pressure ratio, total-to-total
PR	Stage pressure ratio, total-to-total
Pdisch	Discharge pressure, psia
Pt	Inlet total pressure, psia
Ps	Static pressure, lbf/ft^2
POTH	Potential ratio hub, absolute axial velocity at hub/axial velocity at mean radius radius (typical value can be 0.9, or 10% lower velocity at hub)
POTS	Potential ratio shroud, absolute axial velocity at tip/axial velocity at mean radius (typical value can be 1.1, or 10% higher velocity at tip)
RPM cor	Shaft rotational speed, corrected to standard temperature conditions of 518.7 R
Rel Mach	Relative Mach number

THK	Rotor blade thickness, in.
R	Radius from centerline at rotor leading edge, in.
Rg	Gas constant, Universal gas constant/mole weight, for air Rg = 53.35 ft-lbf/R
RPM act	Shaft rotational speed, rotations per minute
Reynolds#	Reynolds number
Slip F	Slip factor
Solidity	Solidity
SCFM	Volumetric flow rate, standard cubic feet per minute (14.7 psia, 518.7 R)
Stator	Setting angle at stator, or inlet guide vane exit, degrees
THK	Blade normal thickness, in
Tt	Inlet total temperature, degrees, R
Ts	Static temperature, R
TR	Temperature ratio, total-to-total
Texit	Total temperature at last stage exit, R
U	Blade peripheral velocity at rotor leading edge, ft/sec
U1 corrected	Rotor peripheral tip speed corrected to standard inlet temperature
W act	Mass flow rate, lbm/s
W cor	Mass flow rate corrected to standard pressure and temperature conditions (14.7 psia, 518.7 R)
Ws1/W2	Inlet tip relative velocity/exit relative velocity
W	Relative velocity, ft/s

Subscripts

1	Rotor inlet (leading edge)
2	Rotor exit (trailing edge)
3	Radial diffuser vane inlet
4	Radial diffuser exit

Introduction

In this paper, several computational tools are used to estimate the effects that ice accretion in the low-pressure compression system has on the engine performance. Here we utilize a representative engine in the 40,000 lbf thrust class and a notional flight trajectory that is appropriate for a commercial aircraft equipped with this engine.

Many of the reported engine icing events (Refs. 1 and 2) occurred at altitude ambient temperatures exceeding the International Standard Atmosphere (ISA) by an additional 18 to 36 Rankin (Fig. 1). In this paper the Numerical Propulsion System Simulation (Ref. 3) (NPSS) code is used. NPSS is an advanced thermodynamic cycle code written in an object-oriented language for system modeling of gas turbine engines. The code provides the overall component-level performance and flow conditions of pressures and temperatures. However, the details within the stages and blade rows are not provided at this level of fidelity. Therefore, COMDES (Ref. 4), a mean line compressor flow code was utilized to provide the flow conditions within each blade row of the multi-stage low-pressure compressor. The COMDES and the NPSS codes were coupled such that they exchange boundary conditions iteratively at each operating point through the flight trajectory. With this combined engine-compressor performance estimation tool, the notional engine is “flown” over the flight trajectory to determine the flow conditions, including the pressure and temperature between each rotor and stator blade row of the low-pressure compressor. Based on preliminary experimental results of ice accretion on a stator vane (Ref. 5), a narrow range of static air temperature from 509 to 515 Rankin was tentatively utilized to identify the stator vane that may be

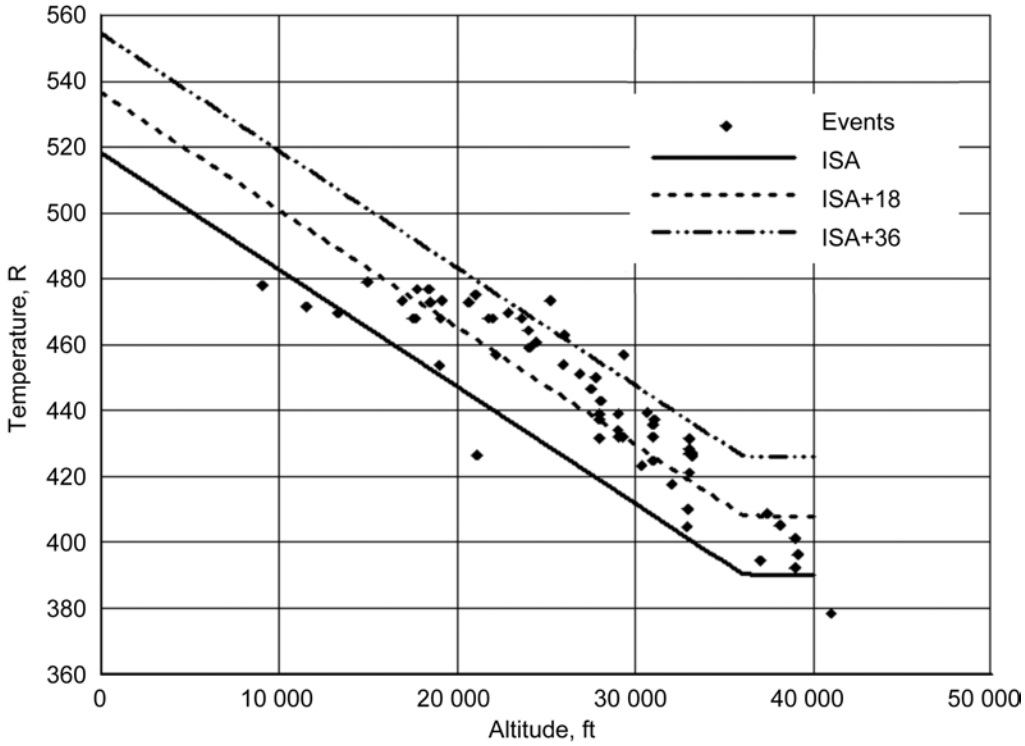

Figure 1.—Engine icing events with International Standard Atmosphere (ISA) and elevated (+18, +36) temperatures plotted (Refs. 1 and 2).

susceptible to ice accretion. However, it is recognized that other parameters such as relative humidity, ice and water content in the fluid and heat transfer coefficient are key parameters that must be considered, but which are not currently included in the NPSS-COMDES code analyses. Therefore, for an initial study on the effects of ice accretion on engine performance, the blockages within the identified compressor stator vane were parametrically varied to estimate the effects on the performance of the low-pressure compressor blade row. This was done throughout the flight trajectory. The NPSS-COMDES computations were run at constant engine thrust at a given altitude.

The flight trajectory includes two cruise altitudes and one descent profile. The first cruise altitude is at 35,000 ft, where the engine thrust is reduced from 100 percent down to 69 percent of maximum thrust at the end of the cruise. The aircraft then proceeds to 39,000 ft where again the thrust reduces from 100 percent down to 79 percent maximum thrust at that altitude. The engine is then spooled back to 10 percent maximum thrust at 39,000 ft as it prepares to descend in altitude. The engine is maintained at 10 percent maximum thrust as it descends to 10,000 ft. This study has determined that there are several potential locations in the flight path where, based on the selected temperature range, icing may occur in the low-pressure compression system.

In order to perform the study, it was necessary to have the details of the LPC geometry to estimate the flow conditions between each blade row with the mean line compressor flow analysis code. To that end, a conceptual design was completed to determine key dimensions within the LPC. Details of the LPC design are provided in the next section in this paper. The baseline engine performance was computed with the NPSS-COMDES code, across the complete flight trajectory. The locations within the LPC where ice accretion could be initiated were determined. At those operating points and locations within the LPC, additional blockage was applied and the NPSS-COMDES code was used to estimate the effects on the LPC and the overall engine performance.

Analysis of the simulation results indicate that as the amount of blockage is increased, the LPC pressure ratio, choke margin, efficiency, and stall margin are reduced. All of these have a net detrimental

effect on engine performance causing an increase in turbine inlet temperature and an increase in the specific fuel consumption.

Once the flow field results from the NPSS code have been completed, they are provided to GlennICE as boundary conditions. GlennICE is a two-dimensional ice accretion code with a model for multiphase ice accretion. Recently (Ref. 6) several changes were made to GlennICE in order to model the ice crystal behavior. Four modifications have been made to GlennICE for handling ice particle impacts. First, there were changes made to the grid inputs to handle internal flows and more complex grid topologies. Second, there are the modifications to the particle trajectory routine that track the energy transfer to and from an ice particle. Third, there is a model for mass loss due to erosion and bouncing in a mixed phase environment. Finally, there are changes to the mass and energy balance whereby the incoming ice particles can add to the ice mass at the surface. In addition to these modifications, an analysis was performed to assess if coupling between the air and ice phases is necessary.

This technical memorandum is a more detailed version of the study that was reported in (Ref. 7), as this report contains the full computational result output listings from the engine system thermodynamic cycle and the compressor flow analysis codes.

Methodology

Design of Fan-Core and Low-Pressure Compressor

Due to the lack of publicly available, non-proprietary engine geometry and performance data, a notional engine was assumed for this study, and a conceptual design of its fan and low-pressure compressor (LPC) was performed. The conceptual design of the fan and LPC was completed by treating the fan as two separate components. This method facilitated the modeling of these regions with the NPSS engine system code, which treats the fan-tip and the fan-core together with the LPC as two separate compressors. Thus, the conceptual design and analysis of the fan-core and the LPC was executed with the mean line flow code as one 5 stage compressor. The 39.25-in.-tip radius fan was sized to accommodate the 1122 lbm/sec flow rate through the bypass duct at the design point. The focus of this effort, however, was on the fan-core and the LPC, since that is the region where icing has been observed to occur in several turbine engines under certain operating conditions. The overall design point objectives for the fan-tip and the fan-core with LPC are described in Table 1. The conceptual sizing study of the fan and LPC flow path was completed with the COMDES mean line compressor flow analysis code. The resulting flow path showing the rotor blade and stator vane leading and trailing edges is illustrated in Figure 2. The key geometric and design point aerodynamic details of the fan-core and LPC resulting from the mean line conceptual design are listed in Appendix A, and the mid-span values of key parameters are summarized in Table 2.

TABLE 1.—THE FAN AND LOW-PRESSURE COMPRESSOR (LPC) DESIGN POINT OBJECTIVES

Fan-tip	
Flow, corrected, lbm/sec	1122
Pressure ratio	1.701
Efficiency	91.1
Shaft speed, corrected, rpm	3761.1
Fan-core and LPC	
Flow, corrected, lbm/sec	172
Pressure ratio	2.23
Efficiency	87.0

Approach

The approach which was deemed best suited for the analysis of the engine was the use of three specialized computer codes. The framework for the engine system analysis was the NPSS code, which provided the thermodynamic cycle analysis of the complete engine system. However, the NPSS analysis by itself would not have provided the fluid condition at each blade row within the multistage compression system, as it typically lumps the entire component into one characteristic performance map. The traditional approach therefore was considered inadequate for the current icing study, since it is critical to model the conditions between each of the blade rows in the LPC. It was decided to utilize the COMDES mean line compressor flow analysis code to determine the performance of each blade row within the fan-core and multistage LPC. This was accomplished by tightly coupling the NPSS code to the COMDES code such that the NPSS code provided the required inlet boundary conditions and shaft speed to the COMDES code. In this new procedure, as the NPSS code is executed at each operating point on the flight trajectory, the COMDES code is executed simultaneously to iteratively determine the overall pressure ratio, temperature ratio, and efficiency of the fan-core and LPC, which are then provided to the NPSS code. As a result of this iterative process, the details of the flow conditions between each rotor and stator of the LPC are also determined.

After the complete flight trajectory has been computed with the combined NPSS-COMDES codes, the conditions of pressures, temperatures, velocities, Mach number, and flow rates at each blade and stator row were provided to the GlennICE ice accretion code for further analysis. The GlennICE code then estimates whether ice accretion can occur at any of the stator vanes of the LPC, at any of the operating points in the flight trajectory.

Flight Trajectory

A typical flight trajectory was generated using the Flight Optimization System (FLOPS) code (Ref. 8) for a commercial aircraft. The flight trajectory illustrated in Figure 3 includes a climb, two cruise

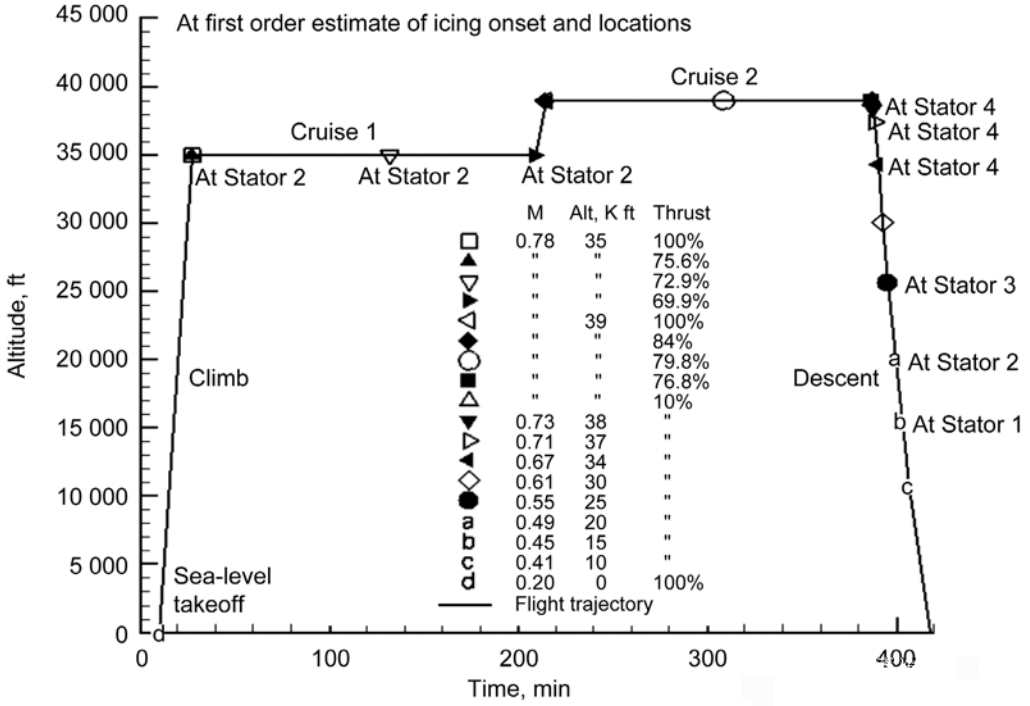

Figure 3.—A flight trajectory consisting of two cruise altitudes and a descent profile. Locations in the flight trajectory are indicated where engine icing may occur at altitude and percent-maximum thrust. Estimated stage stator locations of ice accretion are shown at assumed temperature range.

altitudes, and one descent profile. The detailed output listing of the flight trajectory is included in Appendix B. The first cruise altitude is at 35,000 ft, where the engine thrust is reduced from 100 percent down to 69 percent of maximum thrust at the end of this cruise segment. The aircraft then proceeds to another cruise condition at 39,000 ft where again the thrust is reduced from 100 percent down to 79 percent maximum thrust at that altitude. As the aircraft prepares to go into the descent mode, the engine is then spooled back to 10 percent of maximum thrust at 39,000 ft. Through the remainder of the descent conditions studied, the engine is maintained at 10 percent of maximum thrust down to 10,000 ft. Since most of the suspected engine icing events, due to ice crystal ingestion, have historically occurred during the cruise and descent segments at temperature well above ISA, we focused our analyses on these segments of the flight trajectory. Reducing the thrust during descent to a value lower than 10 percent of maximum thrust put several of the stages in the LPC excessively close to their surge limit. For the analyses that follow the engine was flown initially at an altitude of 35,000 ft at cruise and 100 percent maximum thrust. The ambient temperature at all altitudes was specified as being elevated by 22 Rankin above the ISA (see Fig. 1).

Fan-Core and LPC Baseline Performance Characteristic Maps

Following the conceptual design of the fan-core and low-pressure compressor, the off-design characteristic performance maps were generated with the mean line compressor flow analysis code. Note that this was done separately with the COMDES code in the stand-alone mode, and not with the coupled NPSS-COMDES trajectory analysis code. The compressor performance map was generated in order to illustrate the location of the engine operating points along the vehicle flight trajectory. The fan-core and LPC pressure ratio and efficiency maps generated for the baseline case, without ice accretion. Speed lines from 110 to 40 percent were generated from choke to surge by varying the flow rate. Choke was defined as a point on the speed line where the stage efficiency becomes significantly low to a point where the engine would not be normally operated. Surge was defined as the point where the relative velocity ratio through the rotor reached a peak value near 1.9. The resulting baseline map of pressure ratio versus corrected rotational speed (referenced to a standard inlet temperature of 518.7 Rankin) and corrected flow (referenced to a standard inlet temperature of 518.7 Rankin and pressure of 14.7 psia) is shown in Figure 4. The baseline overall compressor map of efficiency versus corrected speed and flow are illustrated in Figure 5. The plot file of the overall compressor maps shown in Figures 4 and 5 are listed in Appendix C and the complete output listing of the mean line compressor flow analysis code, along the entire baseline performance map is listed in Appendix D.

The compressor operating points with baseline levels of blockage, that is, no additional blockage due to simulated ice accretion, along the engine operating line are superimposed onto the performance maps in Figures 4 and 5, and the corresponding compressor code detailed analysis results are listed in Appendix E. The plot file for the air flow rate, versus overall pressure ratio and overall efficiency of the fan-core and LPC, along the engine operating line, is listed in Appendix F.

Aero-Thermodynamic Engine and LPC Analysis

In this study the computational tools shown in Figure 6 are used to estimate the effects that ice accretion has on the performance of the low-pressure compression system and on the engine. The NPSS code is used for the thermodynamic cycle analysis throughout the flight trajectory. As mentioned earlier, the COMDES mean line compressor flow analysis code is coupled and runs concurrently with the NPSS code. The two codes exchange boundary conditions at every operating point throughout the flight trajectory. The use of the COMDES code eliminates the need for component performance maps that NPSS has traditionally used in order to achieve thermodynamic equilibrium of the engine components at a given operating point. In the mean line compressor code additional blockages can be added to any blade row in the compression system, and their effects on engine performance are calculated and communicated to the NPSS system code.

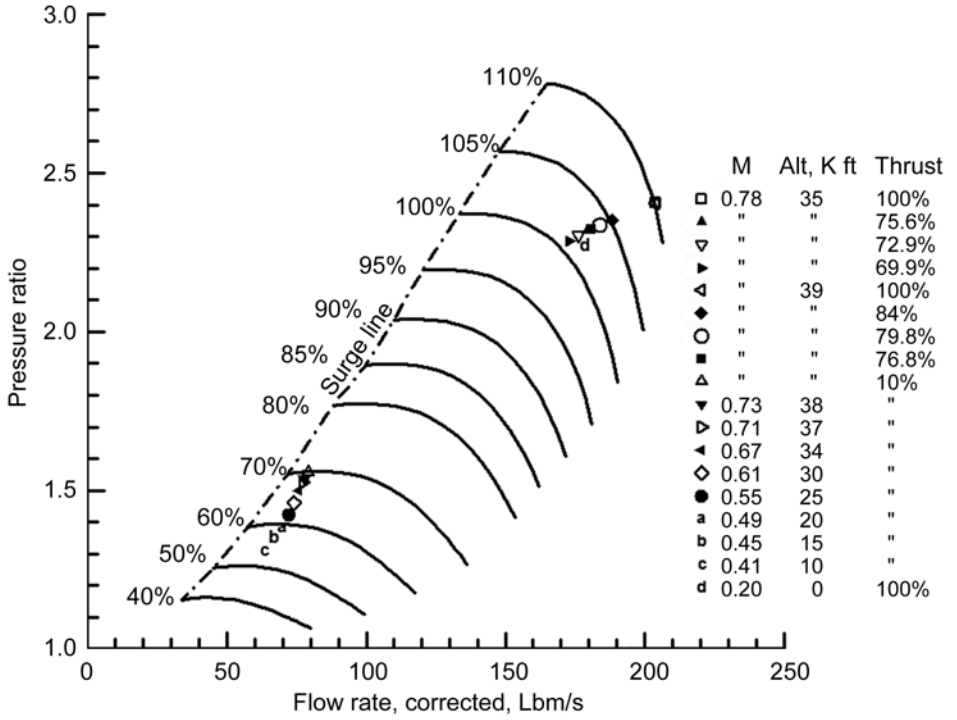

Figure 4.—Fan-core and low-pressure compressor (LPC) stage total pressure ratio versus corrected flow rate for a range of corrected speed lines. Operating points at key locations in the flight trajectory are also indicated on the baseline map.

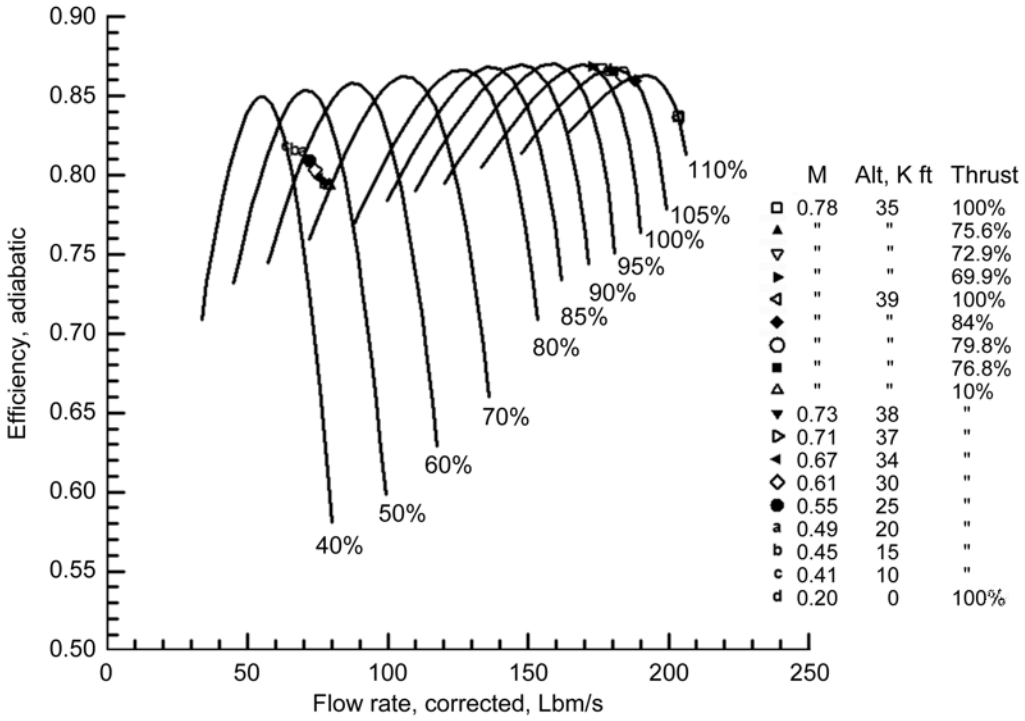

Figure 5.—Fan-core and low-pressure compressor (LPC) stage efficiency versus corrected flow rate for a range of corrected speed lines. Operating points at key locations in the flight trajectory are also indicted on the baseline map.

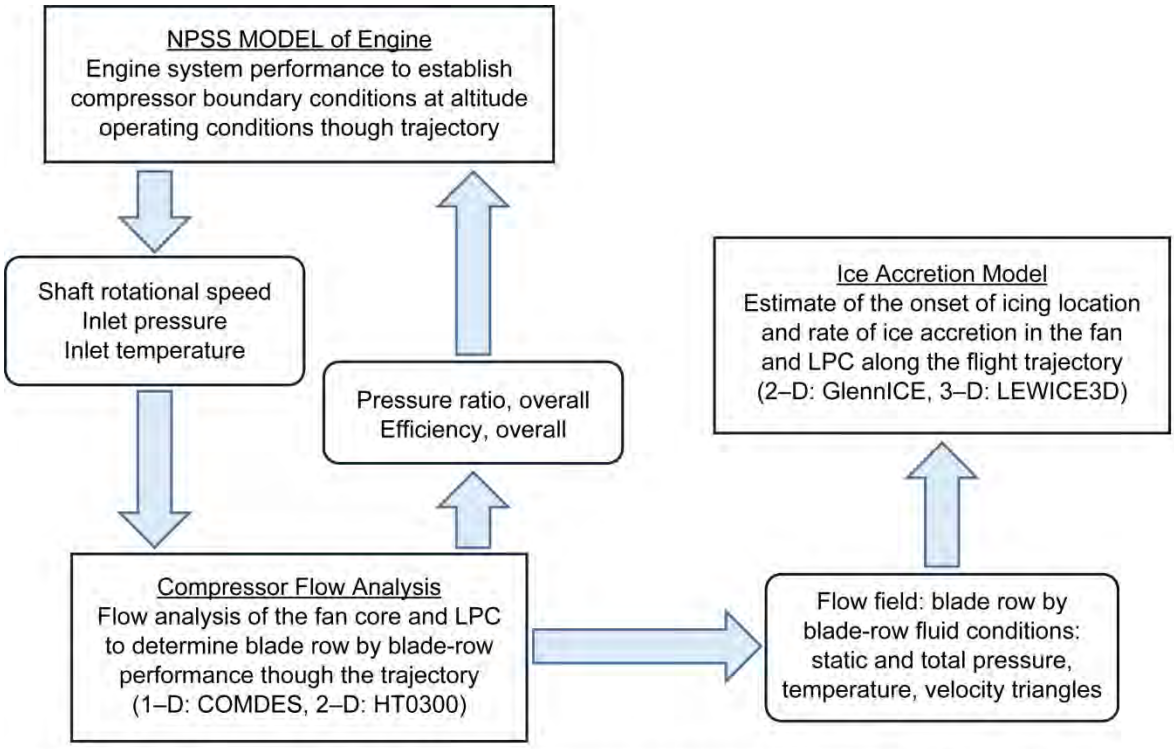

Figure 6.—The approach for the engine icing performance estimation consists of three distinct functions. The codes exchange boundary conditions of key flow conditions such as pressure, temperature, and flow.

An engine system thermodynamic cycle analysis through the vehicle trajectory was computed with the NPSS-COMDES code in order to generate a set of operating points for the baseline case, that is, without any additional blockages due to ice accretion. These results were plotted onto the baseline LPC performance maps in Figures 4 and 5, and also provided as detailed boundary conditions to subsequent analysis with the GlennICE ice accretion code. Appendix G is a listing of the NPSS cycle analysis through the flight trajectory, with baseline blockages.

The next phase of this study involved simulating the effects of ice accretion with the addition of blockage at specific blade rows. Certain assumptions have been made in this analysis. The compression system icing occurs in the fixed components such as the stators, that is, there is no ice accretion on the rotors. However, the wake of the additional ice blockage in a stator is assumed to propagate to the inlet of the downstream rotor, causing an increased level of aerodynamic blockage. Since no limits were placed on the engine analysis through a control module, the engine is operating in a constant thrust mode while blockage is added incrementally at a specific stator, in order to simulate the effects of ice accretion. A static temperature range is assumed where ice accretion may occur. This range, based on preliminary results from laboratory tests (Ref. 5), is between 509 and 515 Rankin. Note that the location and fluid conditions where ice accretion initiates will be further verified by means of the GlennICE analysis, which takes into consideration other effects such as the pressure, relative humidity, and ice-water content of the air throughout the compression system. Other limitations in the application of the NPSS-COMDES analysis codes are also realized. Humidity is not currently taken into account, nor is the multi-phase flow of ice crystals and water droplets considered. These will need to be included in future analyses, in order to improve the codes' performance predictive accuracy in a high ice-water content environment. Currently the unsteadiness effects due to rotor-stator interactions are not considered in either the compressor flow analyses, or the ice accretion model. Therefore, any ice accretion shapes obtained as a result of this study would need further validation.

It has been confirmed in Reference 5 that ice accretes on the vane over time. However, the current study is not considering time directly, that is, it is being performed as a quasi-steady state analysis. The flight trajectory in Figure 3 indicates the stator row which has been identified to have static temperatures within the range assumed to support ice accretion. At that particular stator the aerodynamic blockage is increased from the baseline values parametrically from 10 to 40 percent to simulate the effect that increasing levels of ice accretion can have on the LPC and the overall engine performance.

The engine system analysis of the NPSS cycle code, with parametrically added blockages at select stator vanes, is listed in Appendix H, while the corresponding flow analysis of the fan-core and LPC with the COMDES code is listed in Appendix I.

To gain understanding of how the fan-core and LPC perform within the engine system through the flight trajectory, the overall pressure ratio and efficiency are illustrated in Figures 7 and 8 as a function of additional blockage. It was observed that during the cruise condition at 35,000 ft the compressor efficiency declined sharply as the additional blockage is increased to 27 percent, where it appeared to choke. This resulted in the engine system model unable to run beyond that point. At 27 percent additional blockage, there is a 6 percent reduction in overall fan-core and LPC component efficiency (Fig. 8), resulting in deteriorated engine performance. To maintain constant thrust level of the baseline engine, the engine with simulated ice blockage of 27 percent resulted in a 59 Rankin rise in turbine inlet temperature as shown in Figure 9.

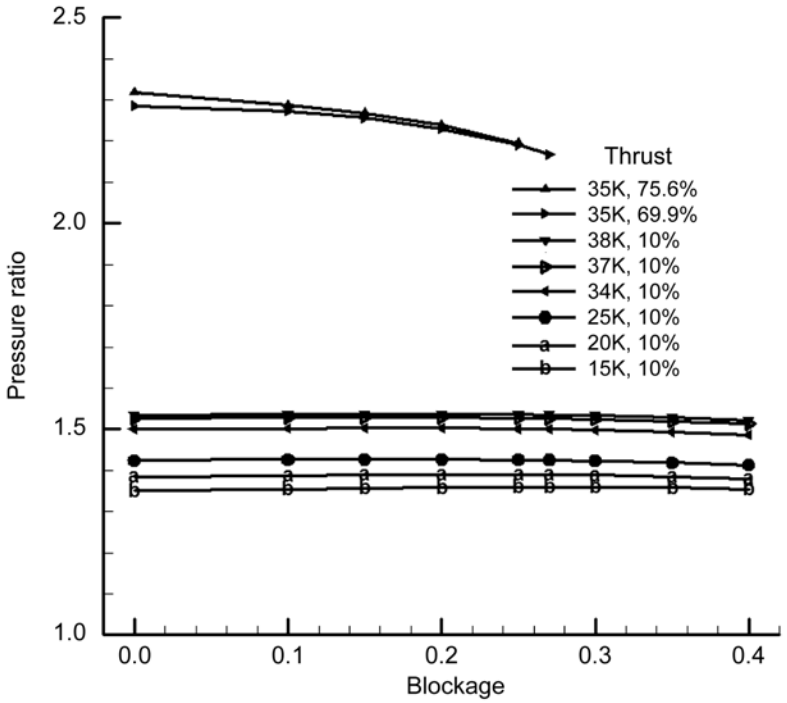

Figure 7.—The effects of additional blockage due to ice accretion on the overall fan-core and LPC pressure ratio along the flight trajectory.

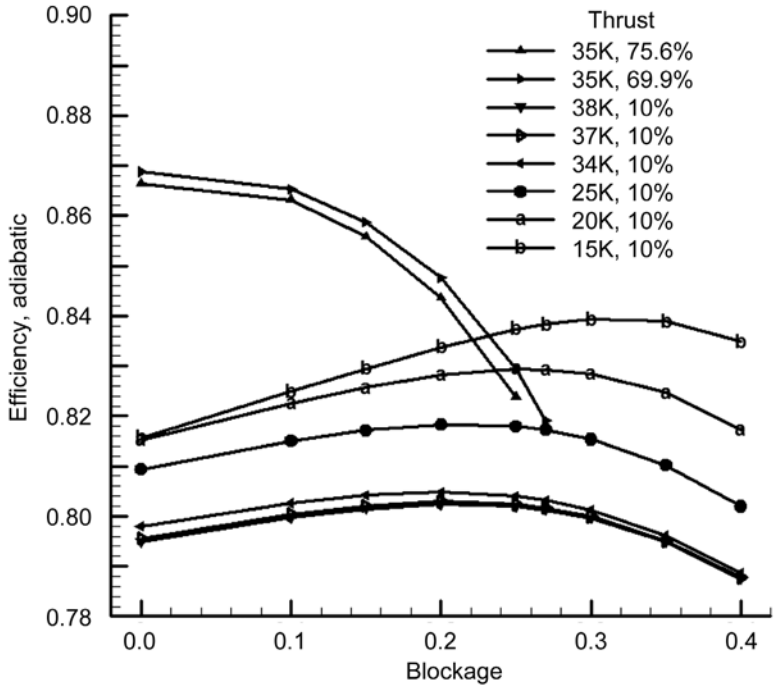

Figure 8.—The effects of additional blockage due to ice accretion on the overall fan-core and LPC efficiency along the flight trajectory.

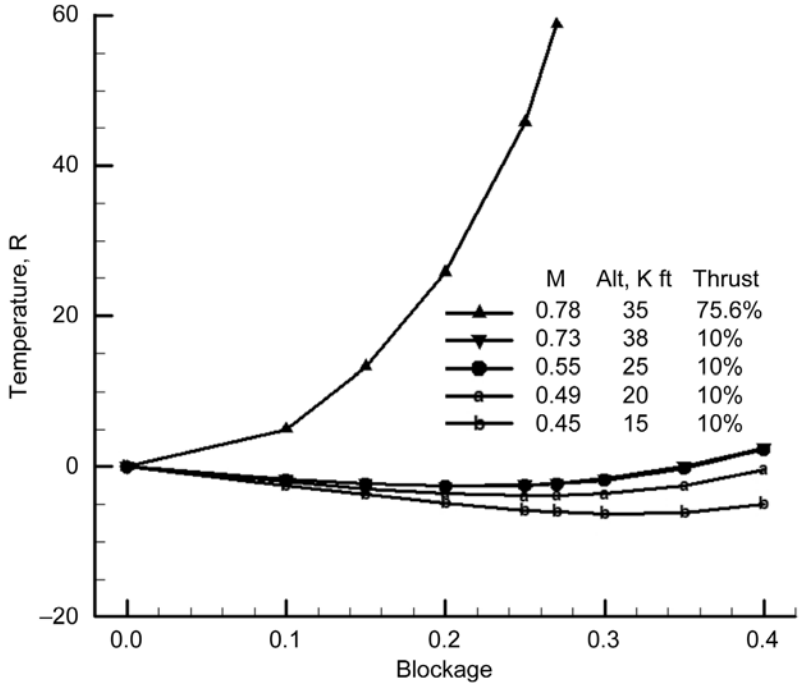

Figure 9.—Effect of additional blockage in the LPC on turbine inlet temperature.

To further understand the effects of blockage on stage efficiency and operability, the individual stage efficiency and relative velocity ratio were plotted with respect to blockage at several key operating points in the flight trajectory, and are illustrated in Figures 10 to 19. During the cruise at 35,000 ft at an engine operating point where the thrust is reduced to 75.6 percent of the maximum, as blockage is increased in the stator of stage 2, the efficiency falls off rapidly in both stages 2 and 3 of the LPC (Fig. 10). Eventually at blockages higher than 27 percent in the stators, the efficiency of stages 2 and 3 fall off rapidly, indicating that they are near choke. Likewise, the rotor relative velocity ratio of stage 3 begins to approach, but does not exceed the surge limit (Fig. 11), since at this operating point, stages 2 and 3 appear to choke before the surge limit is reached in stage 3.

During descent, where the thrust is set to 10 percent of the maximum, the effect of the additional blockage on the fan-core and LPC did not have a significant effect on the overall pressure ratio and its overall efficiency, as illustrated in Figures 12 to 19. In general as the additional blockage increases to 40 percent in the stage that includes the affected stator blade row, the stage efficiency rises then falls. The same effect but to a much greater degree is seen in the adjacent stage downstream. This can be attributed to a temporary improvement in the aerodynamic matching of the stages due to improved incidence angles during all phases of the descent mode, which are at off-design operating conditions. However, as the blockage further increases towards 40 percent, the efficiency begins to decrease. In every instance during the descent segment of the trajectory, the additional blockage causes the stage surge margin limit to be reached or exceeded, effectively causing the engine to experience surge that occurs earlier than in the baseline case without blockage. While additional blockage produces a dramatic increase in the turbine inlet temperature during operation at cruise, during descent, there is minimal effect as was illustrated in Figure 9.

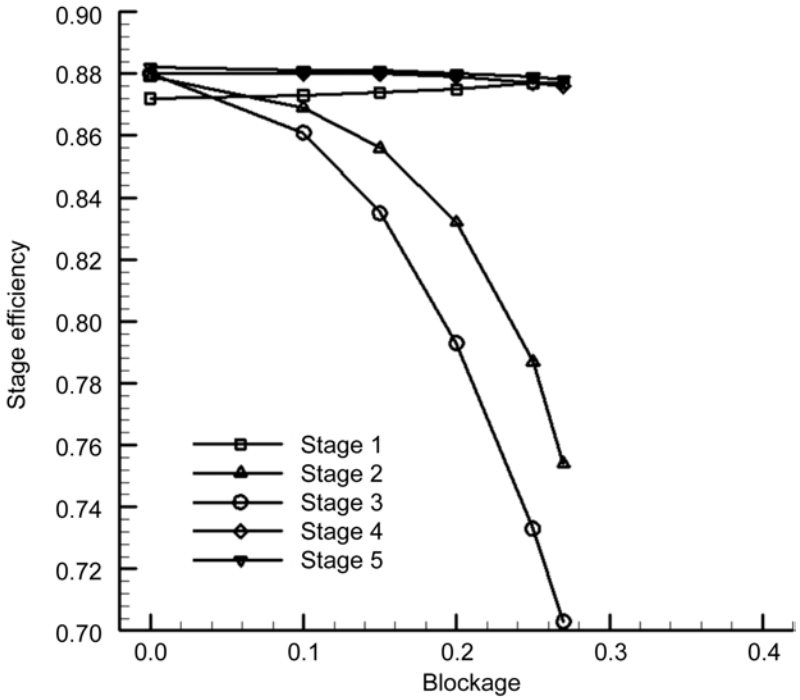

Figure 10.—The effects of additional blockage due to simulated ice accretion applied to the stage 2 stator on the LPC stage efficiencies at a cruise altitude of 35,000 ft with an inlet Mach number of 0.78 and 75.6 percent of maximum thrust.

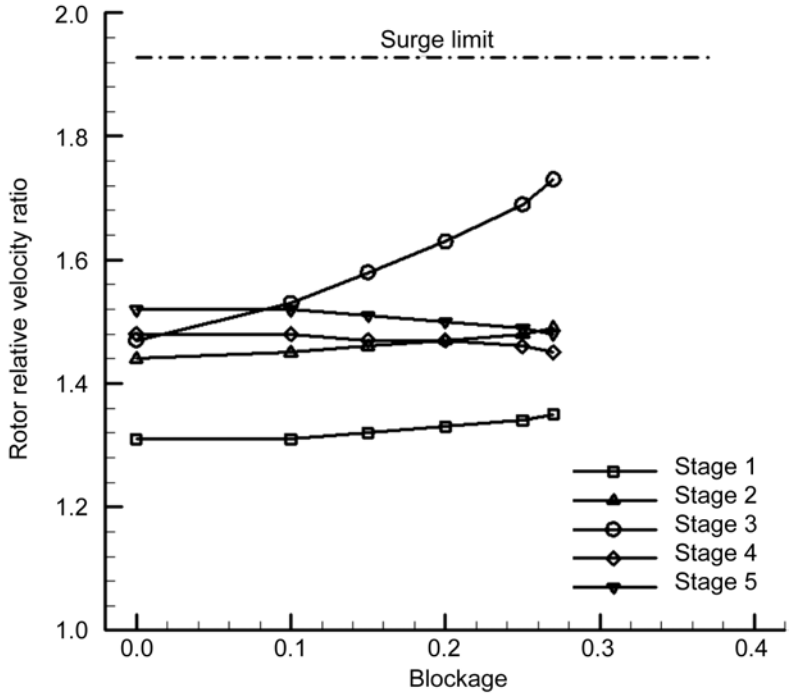

Figure 11.—The effects of additional blockage due to simulated ice accretion applied to the stage 2 stator on the LPC rotor relative velocity ratio at a cruise altitude of 35,000 ft with an inlet Mach number of 0.78 and 75.6 percent of maximum thrust.

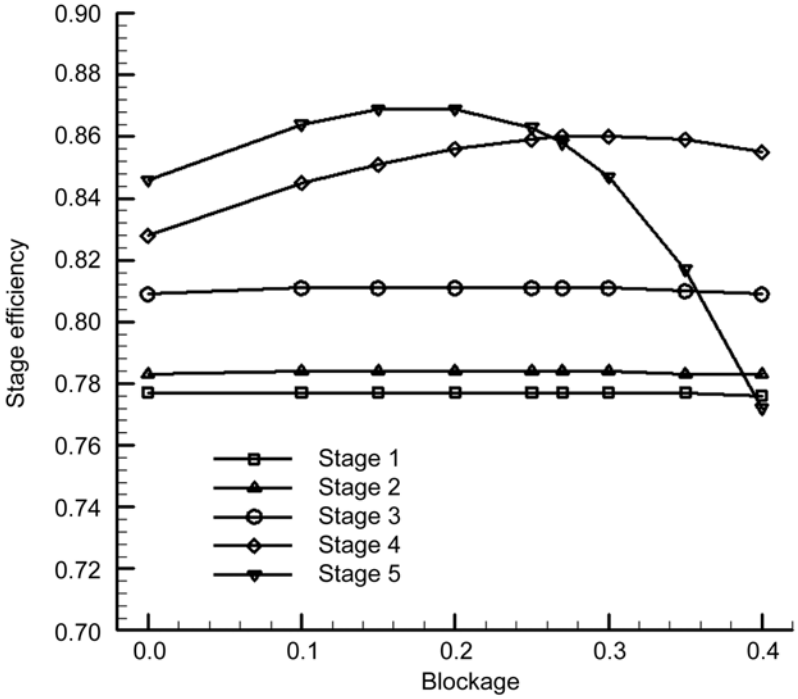

Figure 12.—The effects of additional blockage due to simulated ice accretion applied to the stage 4 stator on the LPC stage efficiencies during descent at an altitude of 38,000 ft with an inlet Mach number of 0.73 and 10 percent of maximum thrust.

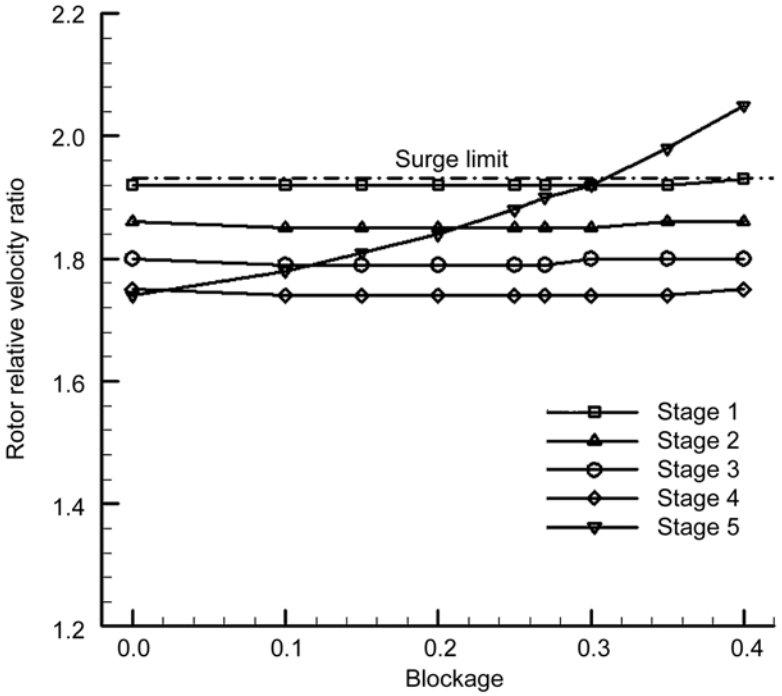

Figure 13.—The effects of additional blockage due to simulated ice accretion applied to the stage 4 stator on the LPC stage relative velocity ratio during descent at an altitude of 38,000 ft with an inlet Mach number of 0.73 and 10 percent of maximum thrust.

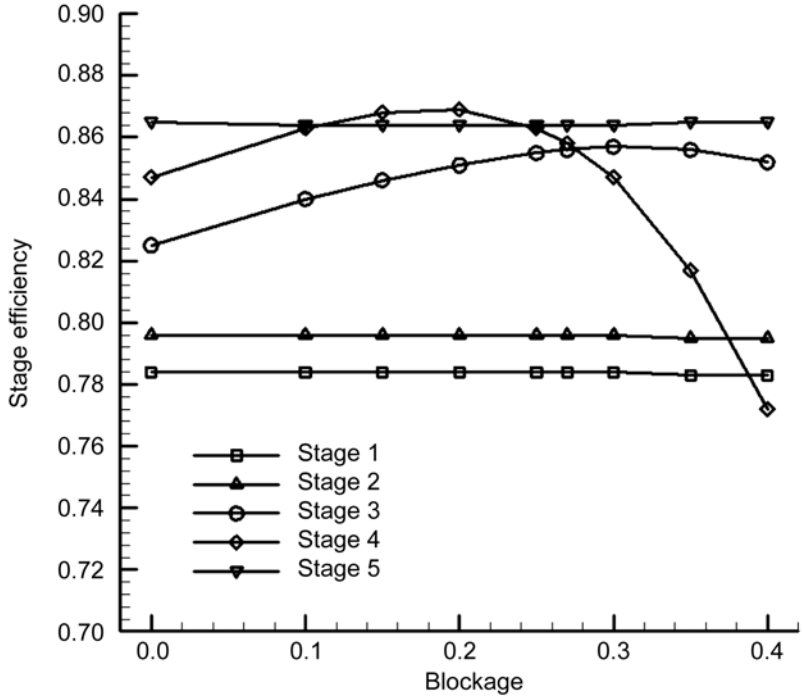

Figure 14.—The effects of additional blockage due to simulated ice accretion applied to the stage 3 stator on the LPC stage efficiencies during descent at an altitude of 25,000 ft with an inlet Mach number of 0.55 and 10 percent of maximum thrust.

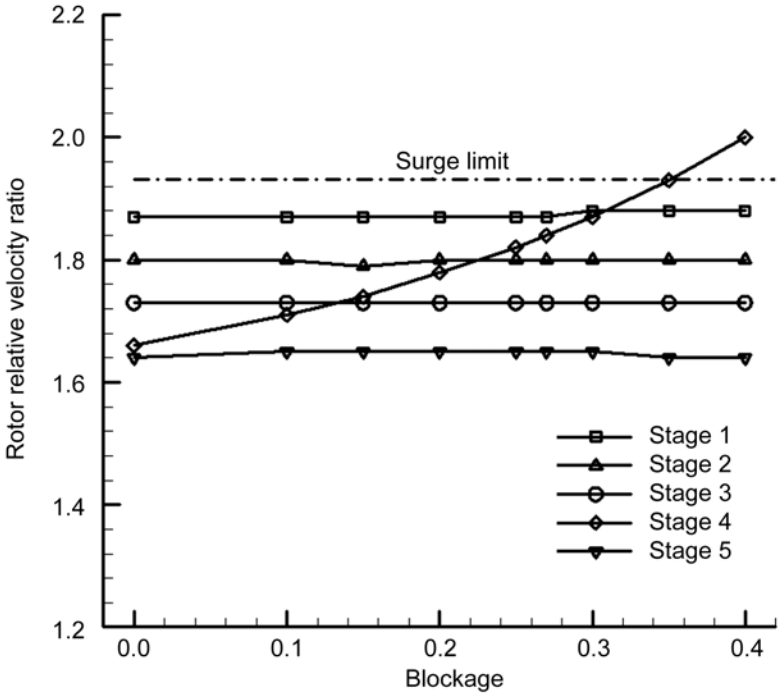

Figure 15.—The effects of additional blockage due to simulated ice accretion applied to the stage 3 stator on the LPC stage relative velocity ratio during descent at an altitude of 25,000 ft with an inlet Mach number of 0.55 and 10 percent of maximum thrust.

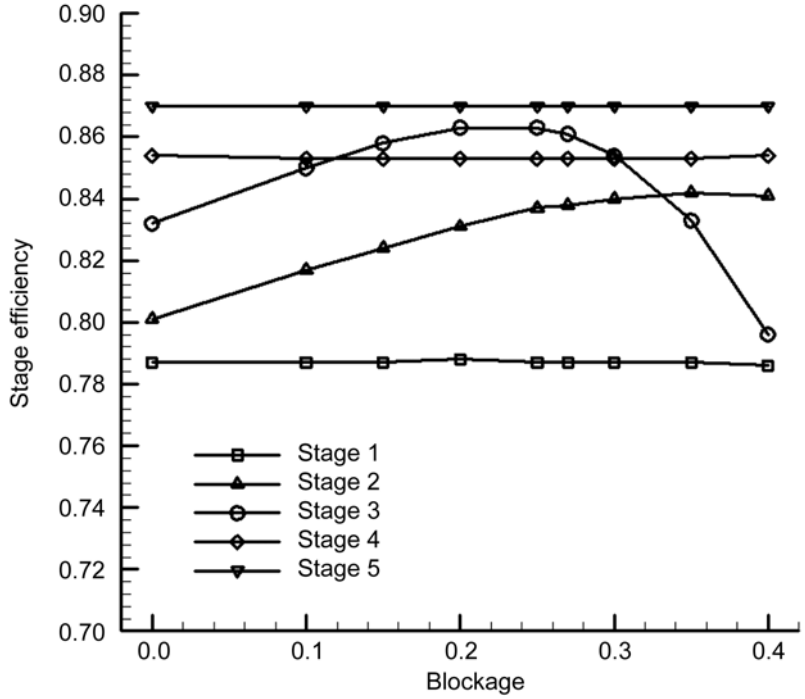

Figure 16.—The effects of additional blockage due to simulated ice accretion applied to the stage 2 stator on LPC stage efficiencies during descent at an altitude of 20,000 ft with an inlet Mach number of 0.49 and 10 percent of maximum thrust.

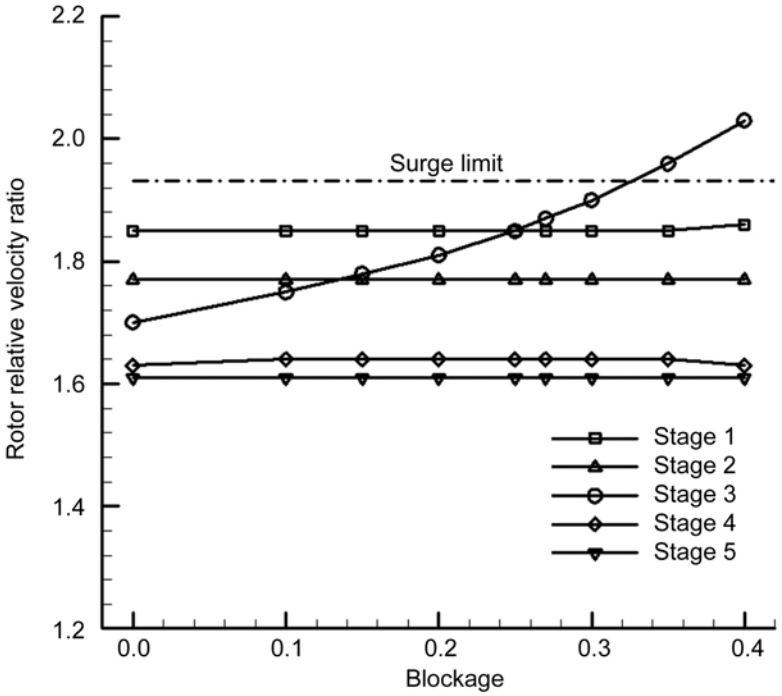

Figure 17.—The effects of additional blockage due to simulated ice accretion applied to the stage 2 stator on the LPC stage rotor relative velocity ratio during descent at an altitude of 20,000 ft with an inlet Mach number of 0.49 and 10 percent of maximum thrust.

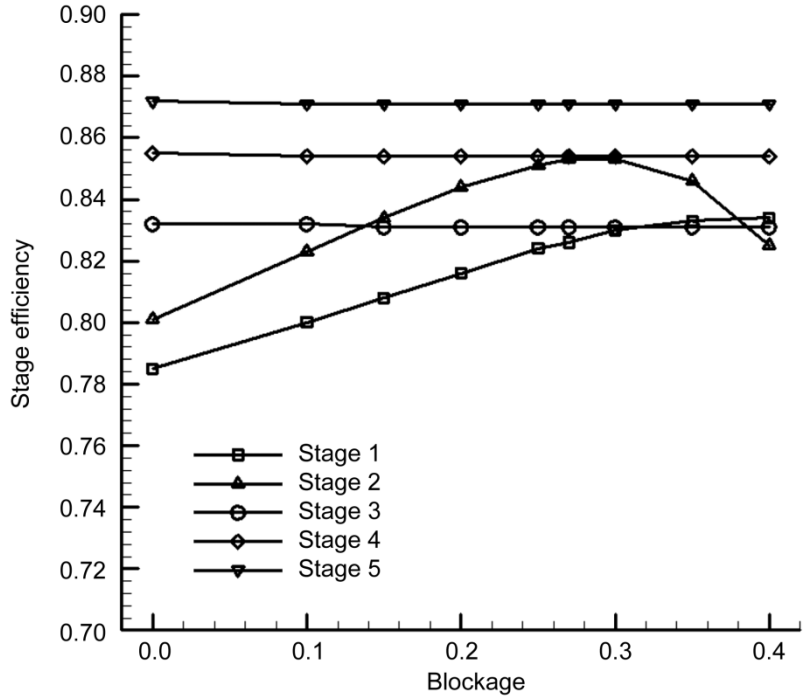

Figure 18.—The effects of additional blockage due to simulated ice accretion applied to the stage 1 stator on the LPC stage efficiencies during descent at an altitude of 15,000 ft with an inlet Mach number of 0.45 and 10 percent of maximum thrust.

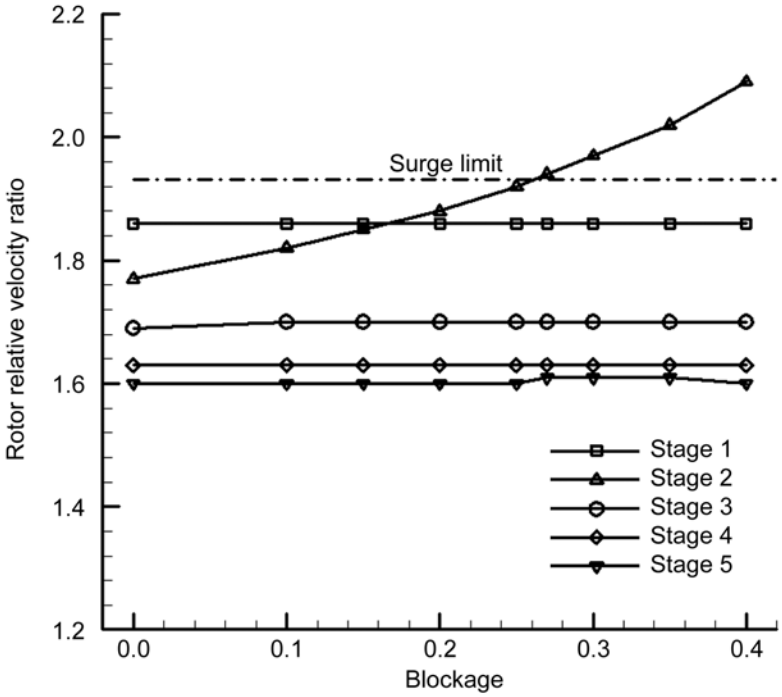

Figure 19.—The effects of additional blockage due to simulated ice accretion applied to the stage 1 stator on the LPC stage rotor relative velocity ratio during descent at an altitude of 15,000 ft with an inlet Mach number of 0.45 and 10 percent of maximum thrust.

As the altitude decreases during descent the potential for ice accretion moves to the upstream stages. As the altitude decreases, the inlet temperature increases, causing the assumed temperature where icing can accrete, to be reached in earlier compressor stages. In order to maintain equivalent thrust levels as that of the baseline engine, the engine system study has shown that during descent mode additional blockage has only a minimal effect on fan-core and LPC pressure ratio (Fig. 7), efficiency (Fig. 8), and likewise on the turbine inlet temperature (Fig. 9) at 25,000, 20,000, and 15,000 ft. Appendix J lists the plot file for Figures 7 and 8 for the overall pressure ratio and efficiency versus parametrically varying blockages along the engine operating line.

Appendix K lists the plot data for the rotor relative velocity ratio and efficiency of each stage with parametrically varying blockages along the engine operating line, as illustrated in Figures 10 to 19.

Parametric Blockage Effect on Fan-Core and LPC Performance Characteristic Maps

To illustrate the sensitivity of the fan-core and LPC performance characteristic to additional blockage in one of the compressor stages, a study was done independent of the engine system. The aerodynamic blockage in one of the stages was varied parametrically from the baseline value, and a complete characteristic map was created using the COMDES compressor flow analysis code. For that study, the stage 2 stator was selected arbitrarily as the location where the blockage was applied, and varied between 10 percent and 40 percent blockage, in 5 percent increments. The resulting overall pressure ratio and efficiency for the fan-core and LPC are illustrated in Figures 20 and 21, and the plot files for the figures are listed in Appendix L. The data for that plot file was obtained from the detailed compressor flow analysis results with the COMDES code through the entire map with parametrically varied blockages in the stator of stage 2, listed in Appendix M. The “blocked” compressor maps in Figures 20 and 21 were created to support a separate activity focused on simulating engine rollback due to ice buildup (Ref. 9). These maps were provided to the researchers who utilized the C-MAPSS40K engine controls modeling code to simulate the engine rollback due to the loss of pressure produced by the fan-core and LPC.

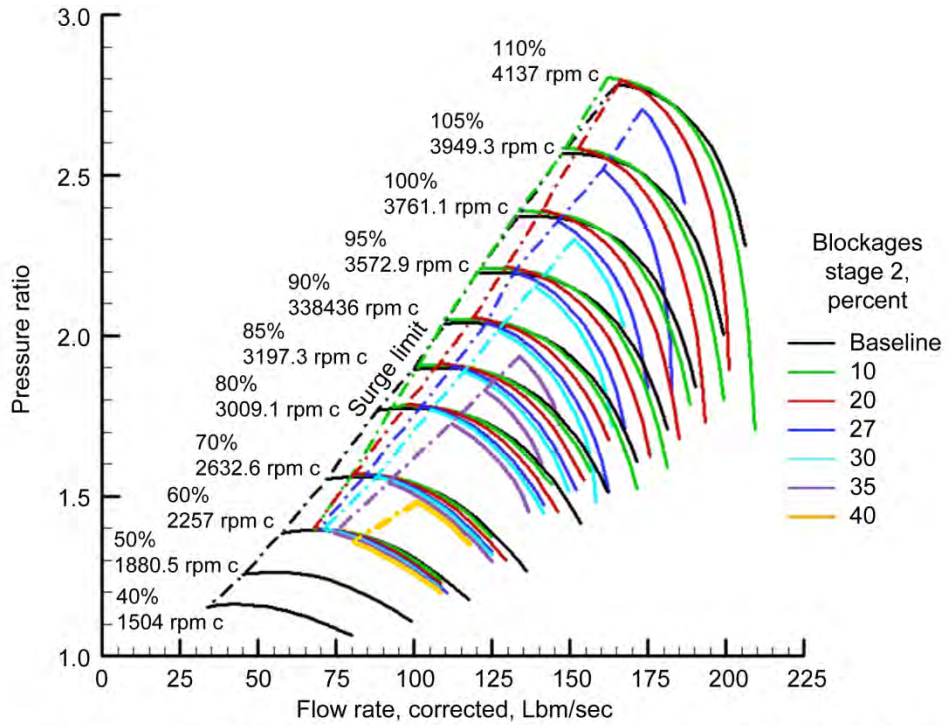

Figure 20.—Overall pressure ratio of the fan-core and low-pressure compressor, as a function of additional blockages applied to the LPC stage 2 stator. Note the reduction in pressure and surge margin, with increasing level of blockage applied to stator 2. (The compressor flow analysis listing is in Appendix L and the plot file is in Appendix M.)

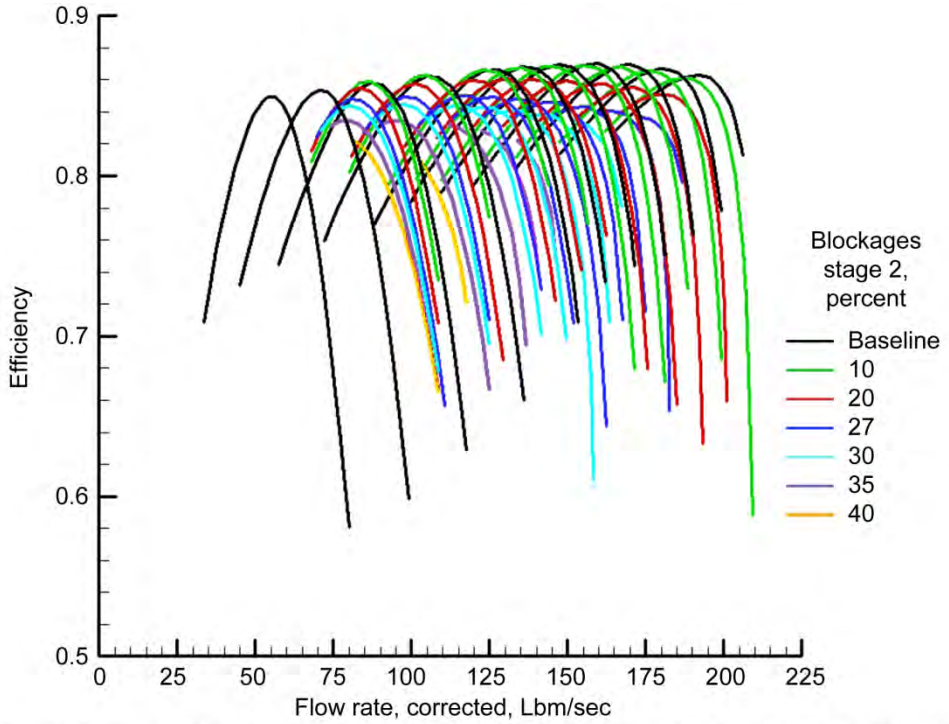

Figure 21.—Overall efficiency of the fan-core and low-pressure compressor, as a function of additional blockages applied to the LPC stage 2 stator. Note the decrease in peak efficiency at all speed lines, with increasing level of blockage applied to stator 2. (The compressor flow analysis listing is in Appendix L and the plot file is in appendix M.)

To better show the effects of additional blockage in the stator of stage 2 on the overall surge and choke margins, the blocked performance of the 100 percent and the 60 percent speed lines are illustrated separately in Figures 22 to 25. Figure 22 illustrates the effect of additional blockage on the overall pressure ratio of the fan-core and LPC characteristic performance at 100 percent corrected speed, while Figure 23 illustrates its effect on overall efficiency along the same speed line. The net effect indicates that as blockage is increased from the baseline value, the choke and surge margins are reduced as well as a reduction in overall efficiency. Figure 24 illustrates the effect of additional blockage on the overall pressure ratio of the fan-core and LPC characteristic performance at 60 percent corrected speed, while Figure 25 illustrates its effect on overall efficiency along the same speed line. At this speed, the net effect indicates that as blockage is increased from the baseline, the surge margin is reduced, but there is less of an effect on the choke margin. However, the effect on overall efficiency along this speed line is most significant with 40 percent additional blockage.

GlennICE

The current accretion analysis is the second phase of this study. The temperature, pressure, and flow rates through the fan and LPC blade rows were provided from the results of the first phase. The purpose of this phase is to analyze the complete flight trajectory with GlennICE to determine whether ice accretion may occur at any of the operating points along the flight trajectory within the fan or LPC.

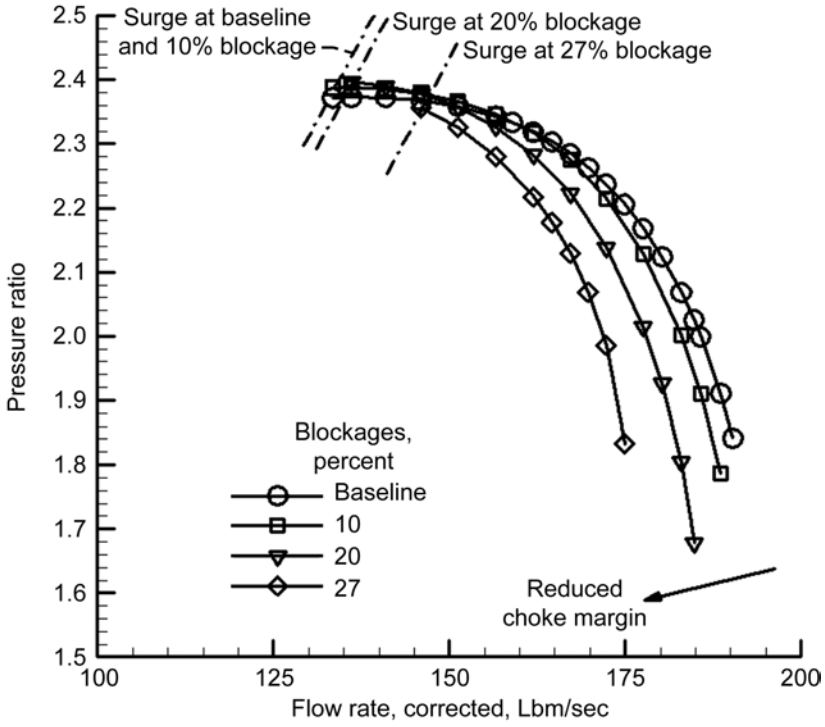

Figure 22.—Overall pressure ratio at 100 percent corrected speed as a function of additional blockages applied to the stage 2 stator in the low-pressure compressor.

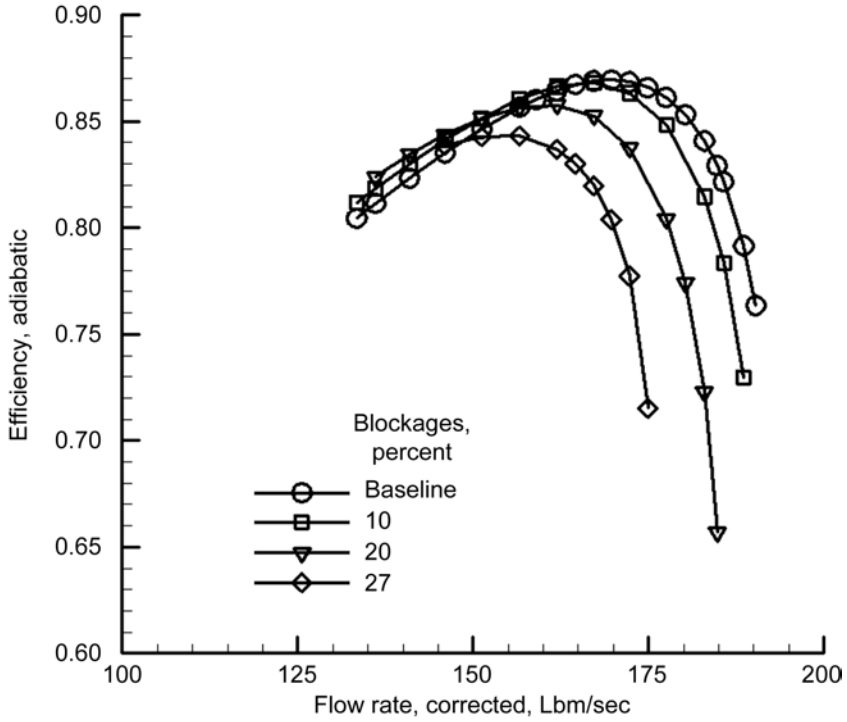

Figure 23.—Overall efficiency at 100 percent corrected speed as a function of additional blockages applied to the LPC stage 2 stator.

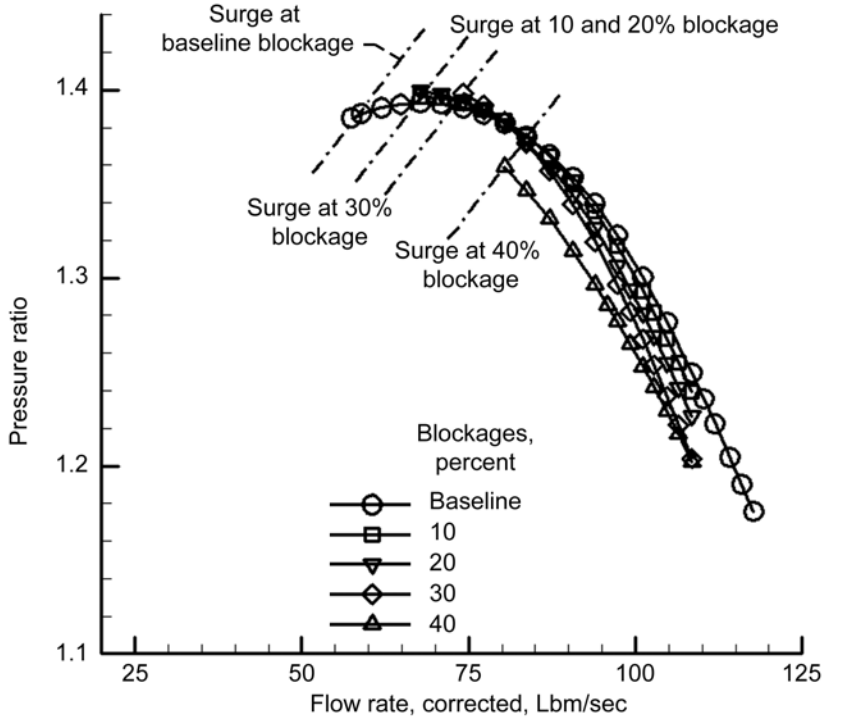

Figure 24.—Overall pressure ratio at 60 percent corrected speed as a function of additional blockages applied to the LPC stage 2 stator.

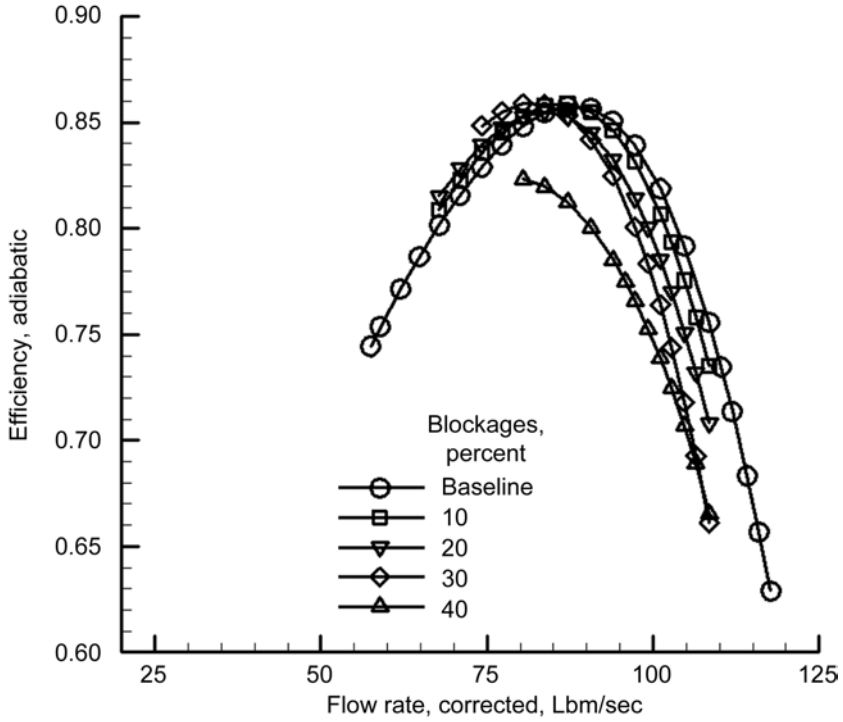

Figure 25.—Overall efficiency at 60 percent corrected speed as a function of additional blockages applied to the LPC stage 2 stator.

The first change to the existing methodology (Ref. 10) was a change in the grid inputs in order to handle more complex grid topologies. In LEWICE 3.2.2, a single block "C-grid" was typically used for most airfoil calculations. Even for multi-element airfoils, the number of grid blocks was held to a minimum. Due to the more complex topography of the internal flow passages typically seen in turbomachinery, additional grid blocks were needed to describe the regions of interest adequately. In addition, LEWICE did not include impacts on grid boundaries. In internal flow, the overall grid boundaries at the top and bottom are walls of the flow path. GlennICE was modified to handle impacts on the internal walls. In addition, GlennICE allows input of single block or multi-block unstructured grids, although this capability is not demonstrated in the current report. As GlennICE was written in FORTRAN90, this allows for dynamically-allocated array sizes. This allows for as many grid blocks and size of grid as are necessary for a given problem.

The second change to the existing methodology was to the equations for particle trajectories. There are two separate modifications to the particle trajectory equations in order to handle ice crystals. First, a separate drag equation is needed. The drag equation for liquid droplets includes an increase in drag due to particle deformation whereas it is assumed that ice crystals do not deform prior to impact. It is also assumed that ice crystals do not breakup due to shear. In addition, drag correlations were added for ice particles that are cylindrical as well as disk-shaped. The second modification was to track the change in particle temperature (and phase change if necessary) through the air stream. Previously, GlennICE did not track droplet temperature as they were assumed to be in equilibrium with the air. However, the mixed phase capabilities have been added to analyze engine ice events. In this scenario, the air, water drops and ice crystals will increase in temperature when they enter the engine. Since the air will respond more rapidly to this increase, there is a driving force for energy transfer between the particles and the surrounding air stream. Additionally, in previous icing analyses, the airflow and particle dynamics were calculated separately, which implies that coupling of the equations were unnecessary. In this regime, it should be clarified whether or not coupling is needed. Crowe (Ref. 11) provided several dimensionless

parameters that could be calculated to determine the necessity of coupling the air and water transport. Mass coupling, momentum coupling and energy coupling (including phase change) were evaluated in a previous report by Wright (Refs. 6 and 10). That report determined that it was not necessary to couple the equations. This allowed for the traditional methodologies to be used whereby the particle trajectories are calculated from the airflow.

The third change to the existing methodology was to the impact of ice crystals with the geometry in question. In LEWICE, particles either adhered to the surface or were splashed according to the supercooled large droplets (SLD) correlations developed previously (Ref. 10). GlennICE included the effects of solid particle bouncing and erosion. For bouncing, when a solid particle hits a surface, the resulting collision is considered elastic or inelastic. If the collision is elastic, none of the incoming energy is absorbed by the surface. For inelastic collisions, some of the energy is absorbed by the surface and some is used to determine the velocity of the particle after the collision. This energy ratio is called the coefficient of restitution. If this coefficient is equal to one, the collision is considered elastic. If this coefficient is equal to zero, all of the energy is absorbed by the surface. In this case, all of the mass must remain on the surface as well. Therefore, in the ice crystal environment being modeled, the coefficient of restitution can be used to determine the fraction of impinging ice crystals that remain on the surface, similar to the splashing model used for SLD.

Higa (Ref. 12) measured the coefficient of restitution for an ice sphere with a 3 cm diameter at velocities up to 0.7 m/s and a wide range of temperatures. Based on his analysis, most ice particle collisions at the surface will have essentially a zero restitution coefficient, meaning that almost all of the energy of the collision is transferred to the surface and the ice crystals are expected to fragment. Initial build up of an ice layer is then caused in part by the kinetic energy of the collision being used to melt the surface ice fragments. GlennICE assumes that the fraction of ice crystals present on the surface will be the fraction of energy transferred to the surface during the collision with the surface. However, this does not necessarily mean that the ice crystals will accumulate. In order for accretion to occur, a liquid water film thickness must be present. Otherwise, the ice fragments would be swept away by the flow field. In the current model, the energy and mass balances are calculated assuming the ice crystals remain on the surface. For control volumes that do not have a liquid film, the ice crystal mass is removed prior to the geometry modification routines. Recent tests (Ref. 6) have provided some initial data on which to base such a model. However, the data from this test is still being analyzed, so a model based on film thickness has not been included in this current analysis.

Erosion effects, however, are accounted for in all regimes. Ice erosion occurs when ice particles hit an ice shape that has already accreted. The force of impact can dislodge portions of the ice shape, especially individual ice feathers. Al-Khalil (Ref. 13) performed tests in the Cox icing tunnel in order to document the mixed phase capabilities of that facility. The model was a 36 in. chord NACA0012 airfoil. All cases were run for 10 min. at 100 knots, angle of attack (α) = 0° and a water median volume diameter (MVD) = 20 μm. Results from that report show that ice impacts can cause erosion of an ice shape in a mixed phase test.

Finally, additional changes included in GlennICE are modifications to the mass and energy balance due to the inclusion of ice crystals. Due to the inclusion of the mass of the impinging ice crystals, the mass balance changes. The energy equation adds the energy from the impacting ice crystals as well as their change of phase. The temperature of water droplets and ice crystals is also transferred from the result of the particle energy balance described earlier. In the solution procedure, the terms other than melting and freezing are summed. Based on the sign of that term, the remaining energy is used to either freeze additional surface water or to melt incoming ice. In a situation where more energy is carried away allowing additional freezing, the freezing fraction of the incoming ice crystals is equal to one and the additional freezing fraction of the incoming water is calculated from the energy balance. In a situation where more energy is available to melt the incoming ice, the freezing fraction of the incoming water is zero and the fraction of incoming ice that is melted is again calculated from the energy equation. In any situation where the sum of the other terms is exactly zero, the freezing fraction of the incoming water is

zero and the freezing fraction of the incoming ice is equal to one. The solution procedure determines the mass of ice or water directly and does not rely on calculating a freezing fraction.

A grid was generated (Fig. 26) and the results from NPSS-COMDES were interpolated at the grid points. Given that GlennICE does not perform a flow analysis, the grid can be somewhat coarser than that used for typical Navier-Stokes analysis, since its only purpose is for tracking particle trajectories. There were 6 grid blocks used with a total of 25,000 grid points in order to interpolate the NPSS-COMDES results to a grid that GlennICE could use. The stators were included in this model as individual airfoils in the flow; since GlennICE solves on a two-dimensional meridional plane, the stators were rotated 90° such that ice could collect near the leading edge if conditions are appropriate. The grid was refined near each stator in order to represent the curvature of the surface more accurately for ice accretion, however, the leading edge is not resolved. Spherical ice crystals of 115 μm MVD were then tracked through this artificial flow field to find collection efficiencies for the geometries where ice crystals impacted. The ice water content was set at 5 g/m^3 and the liquid water content was set at 2 g/m^3 with a 40 μm drop size. The conditions were taken from Case 149 of the NRC test (Ref. 6). The icing time was 30 sec. The conditions shown in Figure 3 result in 17 separate scenarios for ice accretion to occur, which correspond to the engine/compressor operating conditions along the flight trajectory. Table 3 shows the maximum icing rate for these conditions in inches per minute. It should be noted that effects of ice crystal bouncing, erosion, and ice shedding are not included in this analysis which accounts for the large ice accretion on the splitter. The ice shapes on the splitter and stator 5 are shown in Figures 27 and 28, respectively. For this case, the inlet Mach number was 0.78 at 35,000 ft and 75.6 percent of maximum thrust; the static temperature was 416 R and the static pressure was 3.47 psia. Relative humidity was set at 50 percent for all cases. Even with the additional grid refinement, the contours of the stator were not preserved, leading to a square leading edge. Note that this may have increased the collection efficiency.

Future Research

Future research will include using GlennICE to identify ice accretion locations, and iterating with the NPSS-COMDES analyses results obtained in the first phase of this study to parametrically vary the blockage at the identified locations within the LPC. This will estimate the effects on the performance of the LPC and the engine system. Further development of the ice accretion model may include investigating the capability of a higher dimensional analysis, including time dependence due to unsteady rotor-stator interactions and its effect on ice accretion. In addition, a compressor analysis code with higher fidelity capability will be investigated for coupling to the NPSS engine system code. This will provide the ability to specify additional blockages due to ice accretion allowing it to be varied in the span-wise direction. Additional future research will focus on prescribing key engine parameter limits while allowing the thrust to vary. Further improvements are needed in the GlennICE model to better account for bouncing of ice crystals and erosion effects. It will be necessary to refine the grid to determine whether or not the blunt leading edge and loss of stator curvature on the stator geometry due to the sub-optimal grid resolution affects ice accretion.

Summary/Conclusions

A computational tool is being developed for modeling the effects of ice accretion on the performance of the low-pressure compressor, operating in a gas turbine engine system environment. The purpose of this effort is to develop the codes to provide a predictive capability to forecast the onset of engine icing events, such that they could be better anticipated and mitigated. The tool consists of an engine thermodynamic cycle model, a compressor mean line flow analysis model, and an ice accretion model. The tool has been applied to a notional turbine engine to assess the effects of blockage due to ice

accretion through a flight trajectory of a typical commercial aircraft. However, the problem of ice accretion is highly multi-disciplinary since it involves heat transfer from the air to the compressor metal surfaces as well as multi-phase flow, since the air contains ice-water mixtures, which are not directly addressed in the engine system and compressor models. In the first phase, an engine system modeling code and a mean line compressor flow analysis code were utilized to calculate the flow conditions in the fan-core and low-pressure compressor and to identify potential locations within the compressor where ice may accrete. For the blockage study, a narrow temperature range in which engine icing would occur was assumed. This allowed the computational tools to parametrically add blockages to illustrate the effects of ice accretion on the low-pressure compressor blade row performance operating within the engine system environment. This study includes a mean line flow field analyses of the low-pressure compressor and the engine performance during cruise and descent operating conditions at several altitudes within the notional flight trajectory. Ultimately an improved estimation of the location and level of blockage due to icing would be provided by the ice accretion code.

The second phase of this study focused on the ice particle physics in the low-pressure compressor flow field that was computed in the first phase. The results demonstrate that if erosion and ice bouncing effects are neglected, ice accretion mainly occurs on the leading edge of the splitter, which is consistent with results from supercooled large droplet studies. Small amounts of ice accrete on the stators of the LPC. The stage number in which ice accretes on the stator depends on the engine operating condition in flight trajectory. Note that the leading edge and some of the stator curvature is lost due to the coarseness of the grid.

Appendixes

The following appendixes can be accessed from the hyperlinks below or from the bookmarks panel located on the left-hand side of this document.

A.—Design point performance compressor code (COMDES output listing)

B.—Vehicle flight trajectory (FLOPS output listing)

C.—Overall performance characteristic map; plot file data; baseline blockages

D.—Compressor analysis code (COMDES output listing) along map; baseline blockages

E.—Compressor analysis code (COMDES output listing) along engine operating line through flight trajectory

F.—Overall pressure ratio and efficiency; plot file; along engine operating line

G.—Engine analysis (NPSS output listing) through flight trajectory with baseline blockages

H.—Compressor analysis code (COMDES output listing) along flight trajectory; parametric blockages

I.—Engine analysis (NPSS output listing) along flight trajectory with parametrically varying blockages

J.—Rotor Relative Velocity Ratio and Efficiency along flight trajectory versus parametrically varying blockage; plot file data

K.—Stage Pressure Ratio and Efficiency; parametrically varied blockage; plot file; on engine operating line

L.—Compressor flow analysis 110 to 60 percent rpm; COMDES output listing along complete map; with Stator 2 blockages varied parametrically from 10 to 40 percent

M.—Overall performance characteristic map; plot file data; Stator 2 blockages parametrically varied from 0 percent (baseline) up to 40 percent
